Preface

In late 1977, the Turbine Technology Development Group of the Air Force Aero Propulsion Laboratory, identified the need to redesign the AFAPL Heat Transfer Facility's turbine stator blade profile. This report presents the results of my efforts to analytically design a turbine stator which yields optimum aerodynamic performance at transonic flow conditions.

I take this opportunity to thank Dr. Kervyn Mach, Air Force Aero Propulsion Laboratory, for his suggestions and advice during this study. I also wish to thank my thesis advisor, Dr. John R. Shea, for his assistance and direction. Acknowledgement is extended to Dr. James E. Hitchcock and Dr. Harold E. Wright for their counsel in the preparation of this document. I wish to specially thank my wife, Amy, for her encouragement, understanding, and patience during the course of this thesis project.

Finally, I would like to dedicate this report to the memory of my grandfather, Mr. Wilfrid A. Gendron.

Abstract

A turbine stator profile that is analytically predicted to exhibit good aerodynamic performance over a wide range of transonic operating conditions has been designed for the Air Force Aero Propulsion Laboratory's Heat Transfer Facility. Analytical Turbine Design System computer programs developed by General Electric Company were used to generate blade profiles/coordinates and perform 2-Dimensional cascade through-flow calculations (streamline curvature technique). Two aerodynamic performance standards were applied to pressure distribution predictions of the blade contours produced from a parametric variation study; 1) equal flow expansion over both the suction and pressure surfaces, and 2) minimum suction surface/diffusion. The influence of the following geometric parameters upon the design of a transonic turbine stator were investigated; axial location of maximum section thickness, stagger angle, leading edge bluntness factor, and trailing edge taper factor. Results of this study show that a good transonic turbine stator design must have a convergent-divergent flow passage and a flat suction surface aft of the throat location.

THE DESIGN OF A TRANSONIC GAS TURBINE STATOR

I. Introduction

Background

Modern high pressure gas turbines operate in temperature environments in excess of 1055°K (1900°R). Due to the thermal limitations of existing materials, the requirement for blade cooling has become an essential feature of gas turbine design.

The mission objective of the Air Force Aero Propulsion Laboratory's Heat Transfer Facility (Figure 1) is to test and evaluate high temperature turbine blade cooling schemes for advanced turbopropulsion applications. The current test section, a rectilinear turbine stator cascade (Figure 2), was designed during the mid-1960's using a subsonic turbine blade design philosophy. Subsonic blade shapes are characterized by high aspect (span/chord) ratios, and relatively thick profile shapes.

Present day gas turbines are designed to function at pressure ratios which cause the working gas medium to approach sonic flow conditions. These designs are motivated by the high overall thermodynamic efficiency possible with a transonic pressure ratio. Small cross-sectional areas and

Figure 1 Heat Transfer Test Facility Schematic

Figure 2 Schematic of Test Section Cascade

thin trailing edges are generally required to achieve acceptable aerodynamic performance in a transonic flowfield. These requirements must be balanced with the need to permit interior cooling systems while allowing the blade to retain mechanical strength at high temperatures.

Because the heat transfer loads and thermal stresses associated with a transonic profile are substantially more severe than those associated with a subsonic blade shape, relevant test conditions can no longer be established in the AFAPL Heat Transfer Facility. The facility's mission objective is seriously compromised until a new transonic turbine stator contour that simulates modern gas turbine environments is designed.

Problem

The basic intent of this study is to design a modern turbine blade shape that exhibits a high level of aerodynamic performance characteristics in a transonic flow regime. Flow through a transonic cascade passage is subsonic at the cascade inlet, choked at the flow passage throat (minimum area location), and slightly supersonic ($M = 1.17$) at the exit plane. Two tasks associated with the accomplishment of this design objective are: 1) the establishment of aerodynamic performance criteria based upon inviscid, shock-free flowfield calculations, and 2) the development of an analytical design optimization procedure.

The major analytic design tool that will be used to generate and evaluate various blade contours is a set of computer programs entitled, "Turbine Design System" (TDS). Because the codes were recently developed and have not been sufficiently verified for accuracy and consistency, a secondary problem of verifying the TDS programs arises. The computer codes were generated by General Electric Company (Evendale, Ohio) under contract to AFAPL/TBC.

Scope

Experimental testing and evaluation of analytically derived blade geometries are an integral part of this AFAPL Heat Transfer Facility blade design upgrade program. However, it is beyond the scope of this thesis research effort to conduct the experimental portion of the transonic blade development program.

All flowfield calculations and estimates are valid for the mid-span 2-D streamsurface only. Aerodynamic performance and flowfield behavior are predicted for the design point, plus a number of off-design test conditions. The determination of heat transfer loads and mechanical stress analyses are also beyond the scope of this study.

The design point environment can be expressed in terms of the following gas property and velocity vector information: 29.0 N/cm² (42.0 psia) total pressure, 13.1 N/cm² (19.0 psia) back pressure, 1666.3°K (3000°R) total temperature, 1.26 specific heat ratio, 315.0 m²/sec²-°K (1883.7 ft²/sec²-°R)

gas constant, 8.0° gas incidence angle, and 65.0° gas exit angle.

Four geometric shape parameters are varied and optimized during the parametric design process: location of maximum section thickness, stagger angle, leading edge bluntness factor, and trailing edge taper factor. These parameters are defined in Chapter V. Performance sensitivity to off-design gas incidence angle, total temperature, and pressure ratio are also investigated.

Assumptions

A number of assumptions are inherent to the TDS flow-field calculation procedure. The most notable assumptions are: 1) the flow is steady, 2) the flow is inviscid, 3) the flow is isentropic (shock-free), 4) the fluid behaves as an ideal gas, and 5) mass, momentum and/or energy are not transported across a two-dimensional streamsurface.

The first assumption implies that the inlet velocity profile to the test blade is uniform. Because the transition section immediately upstream of the test section is a convergent duct (see Figures 1 and 2) with favorable decreasing pressure gradients, viscous boundary layer growth has negligible effect on the inlet velocity profile. The test section is assumed to be located far enough downstream that any residual freestream turbulence from the upstream combustion process is damped out. A condition of steady, irrotational flow is assumed to exist.

The next assumption is the shock-free flowfield. This assumption breaks down near the trailing edge wake region of the cascade. Viscous effects become significant in this region also. However, shock-free isentropic flow is a reasonable assumption for the rest of the cascade flowfield where velocities are subsonic or slightly sonic and pressure gradients are negative.

Finally, the fifth assumption is applied to a theoretical blade-to-blade streamsurface at the cascade mid-span location. This two dimensional flow assumption is justified on the basis of the rectilinear test section cascade geometry and the symmetrically convergent upstream transition duct.

The accuracy and validity of the experimental data contained in AFAPL-TR-67-147¹ is tacitly accepted. This assumption became a necessary premise during the TDS verification process.

General Approach

The basic approach toward solving the problem of designing a transonic turbine stator via analytical techniques is roughly a four phased process; 1) The flowfield calculation procedure is verified for correctness; 2) Blade design criteria are developed, and the existing blade profile deficiencies are identified; 3) Blade shape parameters are optimized along aerodynamic considerations to yield a final, transonic design; and 4) Off-design performance is investigated.

The first phase of this design project is concerned with establishing the validity of the preceding initial assumptions and the TDS calculation techniques. Verification of the analytical calculation techniques. Verification of the analytical calculation method as well as confirmation of the assumptions is achieved through correlation of subsonic test data¹ for the present airfoil cascade with TDS flowfield predictions. Further substantiation of the TDS program is obtained through comparison of TDS estimates for a transonic flow case with General Electric Company test data, and other analytical prediction programs.

Accomplishment of the phase two objective requires the development of suitable aerodynamic performance criteria. Next, these criteria are applied to TDS generated flowfield predictions for the current blade profile in a transonic flow regime (design point).

Finally, trends are established in phase three between the effect of varying various geometric blade shape parameters and their corresponding influence on aerodynamic performance. A final transonic design results from optimization of the blade shape trends. Off-design cases are also investigated.

Sequence of Presentation

The next chapter, entitled "Analytical Design Methods", contains a brief historical summary of the development of analytical calculation techniques for the turbomachinery

cascade throughflow problem. In addition, a description of the TDS computer design tool developed by General Electric Company under U.S. Air Force contract #F33615-75-C-2073 appears in Chapter II.

The phase one results from the TDS verification process, including correlation of theoretical predictions with experimental data for the current blade design, are presented in Chapter III.

Transonic design operating conditions and performance standards are defined in the first two sections of Chapter IV. These criteria are applied to an analytical prediction of the flowfield surrounding the present design in a transonic environment. The resulting deficiencies and shortcomings of the current blade are then identified and documented in the last section of Chapter IV.

The phase three parametric design study results are discussed in Chapter V. The final design coordinates appear in both tabular and graphical form. Estimates of aerodynamic performance sensitivity to various off-design conditions appear in Chapter VI. The influence of viscous effects on performance is also addressed.

Conclusions and recommendations for further study are offered in Chapter VII.

II. Analytical Design Method

The design of turbomachine cascade sections has traditionally been based upon empirical relations and/or one-dimensional flow analyses. Thus, the standard practice for the design of compressor and turbine cascades has primarily consisted of a "build and try" approach. The advent of advanced gas turbine engines for aircraft application, along with their staggering development costs and stringent performance requirements (high temperature operation, lightweight, high thermodynamic efficiency), has necessitated a revolutionary change in compressor and turbine design procedures. Today, the performance of modern designs is analytically predicted before a commitment is made to proceed with an expensive fabrication and test program. Large, high speed, digital computers have made this approach more attractive from a cost effectiveness standpoint.

Pursuant to the goal of analytically predicting turbomachine cascade performance, a substantial number of investigators from industry, government, and academia, have developed cascade through-flow calculation techniques. Therefore, one objective of this chapter is to present an overview of the various methods currently used to compute turbomachine cascade flowfields. However, the basic intent of this section is to provide a detailed description about the nature and operation of the major analytical design tool (i.e., the

TDS computer programs) that will be used to generate new transonic blade profiles and to determine the corresponding cascade flowfield characteristics.

Cascade Through-Flow Calculation Techniques

The cascade through-flow problem is three-dimensional, time-dependent and viscous in nature. Most modern analysis techniques dealing with three-dimensional cascade flowfields are based upon an approximate method set forth by Wu² in 1951. Wu's paper is primal to the field because he was one of the first investigators to make the necessary assumptions and simplifying approximations for transforming the overall three-dimensional problem into a series of two dimensional computations.

Wu's basic through-flow theory proposes that the three-dimensional flowfield should be modeled as a set of two-dimensional flows; one of these flows is located in blade-to-blade surfaces (the S1 stream surfaces), while the other flow lies on hub-to-shroud surfaces (the S2 stream surfaces). The relative orientation of the S1 and S2 stream surfaces is depicted in Figure 3.

Two classical solution approaches to the problem of calculating flows on either the S1 or S2 stream surfaces are reported in literature; the matrix method, and the streamline curvature method. Iterative numerical techniques are an inherent feature of both solution procedures. Iterative methods guess an initial stream function/velocity distribution from which the rest of the fluid properties in the flowfield are

Figure 3 S1 and S2 Stream Surfaces

determined. The equation of motion is solved by either the matrix or streamline curvature approach, and thus, a new velocity field is predicted. This iterative process continues until a set of specified convergence criteria are satisfied.

Wu^{2 3} suggested the use of matrix methods. In this type of approach, sometimes referred to as a finite-element method, the iterations are performed on a fixed set of grid lines. The matrix method has recently been used to compute cascade flowfields by Bosman and El-Shaarawi⁴, Bosman⁵, Katsanis and McNally^{6 7}, and others^{8 15}. Gopalakrishnan and Bozzola¹⁶, and McDonald¹⁷ pose the through-flow problem in time dependent form and use finite-element techniques to solve for transonic flows in turbomachinery cascades. Ives and Liutermoza¹⁸ use conformal mapping techniques in conjunction with a finite-difference grid to obtain transonic cascade solutions.

In the streamline curvature method, the grid is composed of the streamlines themselves and a set of semi-orthogonals.

During the iteration sequence, the grid lines and points are repositioned after each iteration to satisfy mass, momentum and energy balances. Novak and Hearsey¹⁹, Smith²⁰, Frost²¹, and Wilkinson²² have reported the development of computer programs which employ streamline curvature techniques.

The concept of quasi-three-dimensional, numerical solutions of flow through cascades refers to the simultaneous solution of flow on the S1 and S2 streamsheets. A number of investigators^{4,19} use coordinated computer programs in which the S1 stream surface shape is dependent on the S2 solutions while the S2 shape is dependent on the S1 solutions. These methods are indicative of the state-of-the-art and have established good convergence for steady, inviscid and subsonic flow conditions.

Turbine Design System (TDS)

The specific intent of this research is to establish an analytical procedure for designing transonic turbine blades. Fundamental geometric blade shape parameters were identified, and the influence of these parameters upon cascade performance for a given set of operating conditions was determined. The final design is simply the geometric parameter set which yields the highest amount of aerodynamic performance.

A parametric variation and evaluation study was conducted to realize the basic intent outlined above. The major analytical tool that was used to accomplish this study is the Turbine Design System (TDS) computer programs developed by

Figure 4 TDS Schematic Diagram

General Electric Company under contract to AFAPL/Turbine Components Branch. Two TDS subprograms were utilized: the BLDDDES and CASC modules.

Given a relatively simple blade shape definition, the Blade Design (BLDDDES) module generates an output file with a standardized set of blade shape coordinates and surface curvature information. The Cascade Analysis by Streamline Curvature (CASC) module returns the inviscid, shock-free flowfield solution for a cascade of airfoils defined by the BLDDDES output file. Figure 4 is a schematic diagram which graphically displays the function and role of each module.

Further information about the operation of the TDS computer programs can be found in the TDS User's Manual²³ and AFAPL TR-78-92²⁴.

BLDDES MODULE. Two modes of data input to the BLDDES module are possible. Input may consist of a parametric blade definition or as an array of digitized blade coordinate data taken from a layout drawing or design report. The latter mode of data input was used to obtain a standardized definition of the current test blade profile. This information was required to perform the TDS verification process (Chapter III) and to arrive at an analytic evaluation of the current blade at transonic operating conditions (Chapter IV). The parametric definition input mode option was utilized to generate blade profiles for aerodynamic analysis during the parametric design study (Chapter V).

The standard definition returned by BLDDES is composed of blade surface coordinates that are tabulated with respect to the blade section stacking point. BLDDES output is consistent with the input requirements for the aerodynamic analysis module; CASC.

CASC Module. The CASC module yields steady-state, inviscid, shock-free flow solutions for a cascade of airfoils. CASC solutions for any particular blade section will lie on the blade-to-blade S1 streamsurface normal to the blade (see Figure 3).

The streamline curvature calculation technique employed by CASC requires the input of accurately determined boundary

surface coordinates from the standardized BLDDDES output \$BB Namelist. The position and curvature of the streamlines are found such that the continuity equation, the cross-stream momentum equations, and the boundary surface curvature information are satisfied.

Although the inviscid assumption costs CASC a small amount of inaccuracy, it reduces the complexity of the calculations considerably. CASC's main asset is that it requires substantially less central processor time and core space to process a given airfoil contour as compared with other aerodynamic analysis programs reported in literature. Thus, the "quick-look" capability offered by CASC makes the program ideally suited towards performing a parametric design study involving a number of cases to be analyzed.

III. TDS Verification Investigation

Purpose

Verification of the General Electric TDS computer programs was included as a major step in this research study for two reasons. First, the TDS codes had been recently procured by the U.S. Air Force in November 1977, and had not been sufficiently verified for accuracy and consistency. Second, it was necessary to determine whether or not the Heat Transfer Facility's rectilinear cascade geometry along with the simplifying inlet velocity profile assumptions could be analyzed by TDS to yield accurate results.

Pressure distributions for the existing turbine airfoil were experimentally determined by Quick, Henderson, and Tall during a 1967 cold-flow investigation study. The results are tabulated in AFAPL Technical Report 67-147¹.

Hence, the overall TDS verification objective was to obtain pressure distribution predictions for the present blade geometry that match available experimental data at two different sets of operating conditions. Comparison of analytical TDS pressure distribution predictions with actual Heat Transfer Facility experimental data was expected to substantiate the validity of the initial assumptions and the computer programs.

Procedure

The general approach used to verify the TDS programs consisted of three distinct phases. First, thermodynamic and geometric boundary conditions, as well as an inlet velocity profile, were specified for input into the TDS programs. These boundary conditions were chosen so that they were a direct reflection of the test conditions under which the experimental data were obtained.

Next, verification criteria were developed. In theory, the analytical codes should yield matching pressure distributions for the two known sets of test conditions that were considered. Additionally, the computer programs should yield predictable flowfield solutions for small variations of the inlet boundary conditions.

Finally, the results of the verification investigation were evaluated. The conclusions are presented in the last section of this chapter.

Boundary Conditions

Thermodynamic. During the 1967 experimental cold flow investigation of the present turbine airfoil¹, pressure distributions were obtained for various gas operating conditions. Two of these cases were selected for analytical correlation purposes. The thermodynamic properties for each of the two cases are tabulated in Tables I and II.

Geometric. Establishment of geometric boundary conditions for aerodynamic analysis by the CASC module consists

of defining the current blade profile, and then standardizing the definition with respect to a stacking point origin via the BLDDDES module. The portion of the BLDDDES input \$BB namelist (FORTRAN) that defines the present turbine airfoil shape appears in Table III. Figure 5 is a scaled drawing of the existing turbine airfoil section.

The philosophy used to define the current blade section is the following; 1) represent the leading edge as an ellipse, 2) represent the trailing edge as a circle, and 3) input the pressure and suction surfaces as digitized coordinate pairs. This philosophy becomes obvious when the quantities contained in Table III are clarified in the following paragraphs.

The pressure and suction surfaces are defined by the (X,Y) pairs in the PRESS and SUCTN arrays. These coordinates are taken from the original Allison Division blade design report²⁵. The coordinate system that was employed fixes the X-axis parallel to the axial centerline, positions the leading edge highlight point at (0,3), and the suction surface is the upper surface.

ISTK is the stacking point indicator. A value equal to unity locates the stacking point at the center of gravity of the airfoil section. The choice of stacking point location is academic; since choice of any stacking point location will yield identical stacking results for a rectilinear two-dimensional cascade.

A zero value for IVANE notifies the software logic that the airfoil has a blade input orientation, i.e., the suction

side is uppermost. LEDGE equal to one means that the PRESS and SUCTN coordinate arrays do not include the leading and trailing edge. BLDDDES will then generate an ellipse for the leading edge while either a square or circle will be fitted to the trailing edge.

ITMODE is the trailing edge shape indicator. A value of one causes the BLDDDES programming to define the trailing edge as a circle with diameter equal to the trailing edge thickness (TE). From a plot of the original design coordinates, the trailing edge thickness, TE, was determined to be 0.2117 cm (0.08335 in).

The eccentricity parameter, E, is the ratio of leading edge ellipse semi-major to semi-minor axes. After a plot of the blade was made from coordinate data and several iterations were performed to obtain the best curve fit, a value for E of 1.45 was determined. EPSI is an estimate of the leading edge ellipse semi-major axis inclination angle.

SCALIN defines the scale size of the input data. Actual coordinates were used. ZLE and ZTE refer to the axial location of the leading and trailing edge highlight planes. RLE, RREF, and RTE are the radii which define the airfoil section radial location in a hypothetical curvilinear engine. Because the facility test section is rectilinear, a large radius value was chosen to simulate this condition. Thus, a radius value of 60.638 cm (23.87324 in) was chosen along with 100 blades (NBLDS) to yield a pitch value of 3.81 cm (1.5 in) which is the blade spacing in the two-dimensional cascade.

Inlet Velocity Profile. A condition of steady, turbulent, and fully-developed flow has been assumed to exist at the test section inlet. Because fully-developed, turbulent velocity profiles are characterized by fairly uniform core regions, the test blade inlet velocity profile is a set of constant, uniform velocity vectors. The direction of the velocity vectors is the gas incidence angle, β_1 , and the magnitude is expressed in non-dimensional form as the inlet Mach number, M_1 .

Due to the geometry of the upstream transition section, a slight gas incidence angle is known to exist. The gas incidence angle is estimated to be $8^\circ \pm 8^\circ$. As will be shown in the theoretical development of the third verification criterion, small gas incidence angles ($\pm 15^\circ$) have negligible effect on the pressure distribution of an airfoil in a turbine cascade. Therefore, the amount of error associated with $\pm 8^\circ$ is insignificant. Because gas incidence angle is primarily a function of hardware geometry and not gas operating conditions, it is assumed to remain constant for both experimental cases under consideration.

The inlet Mach number was approximated for each case through application of the following one-dimensional, isentropic equation;

$$\frac{\dot{m}}{A} \sqrt{\frac{T_{0R}}{\gamma g_c^2}} \frac{1}{P_0} = M_1 \left(1 + \frac{\gamma-1}{2} M_1^2 \right)^{\frac{\gamma+1}{2(1-\gamma)}} \quad (1)$$

where \dot{m} is the mass flow rate, A is the cross-sectional area normal to the flow, T_0 is the total temperature, R is the universal gas constant divided by the molecular weight of air, γ is the specific heat ratio, and P_0 is the total pressure. When the appropriate Table I and II values are inserted into equation one, along with a cross-sectional area of 148.4 cm^2 (23 in^2), the inlet Mach number is estimated to be 0.29 and 0.30 for cases one and two respectively. Because of the significant amount of error associated with the figures for mass flow rate and the cross-sectional area normal to the flow, these approximations are only useful as a general estimate of the inlet Mach number level. Therefore, a number of cases with varying inlet mach numbers were analyzed before a precise analytical-experimental correlation was reached.

The case one and two BLDDDES output files (CASC input files) which contain the standardized blade definition of the existing airfoil, plus the respective thermodynamic and inlet velocity profile boundary information, are listed in Appendix A. Further explanation of the Appendix A \$BB namelist variables can be found in the TDS User's Manual²³.

Standards

Criterion One. For a given input combination of thermodynamic, geometric and inlet velocity profile information, the CASC module returns a value for the cascade exit static pressure, P_2 , the gas exit angle, β_2 , plus a listing of the

airfoil pressure distribution. For each of the two test cases, the first verification criterion requires that the analytical pressure distribution prediction matches the experimental data. Analytical-experimental correlation must occur for the boundary conditions stated in the previous section, plus a small change in the inlet Mach number value.

Since the exit static pressure, P_2 , must equal the cascade back pressure, P_b , for a subsonic cascade operating condition, the exit static pressure is equal to the atmospheric pressure, plus exhaust duct line losses, ΔP ;

$$P_2 = P_b = P_a + \Delta P \quad (2)$$

Because case one is at a lower mass flow rate operating condition than is case two, lower exhaust duct exit velocities will exist during case one. Thus, the line pressure losses are expected to be less for case one. In addition, the line pressure losses for either case should be greater than zero, but less than 20 percent of the atmospheric pressure level. Therefore, another requirement of the first verification criterion is that the following inequality must be satisfied;

$$0.0 < \Delta P_{\text{case one}} < \Delta P_{\text{case two}} < 0.20 P_a \quad (3)$$

Criterion Two. The gas exit angle, β_2 , is primarily fixed by the cascade blade outlet angle, α_2 . The blade outlet angle is defined in Figure 6 as the angle formed by

Figure 6 Turbine Cascade Control Volume

the tangent line to the trailing edge camberline and the axial chord line. The existing turbine cascade has an outlet blade angle of 61.2° .

In most turbine and compressor cascades, a slight gas deviation angle, δ , will exist. Gas deviation angles for subsonic cascades are small and result from the pressure equilibrium process that occurs in the trailing edge wake region of the blades. Vincent²⁶ estimates that deviation angles are $\pm 2^\circ$ for most turbine cascades. Cox²⁷ reports deviation angles of the order of 5° from cascade test data.

Hence, the second verification criterion requires that the gas exit angle computed by CASC be equal to $61.2^\circ \pm \delta$, where:

$$-5^\circ < \delta < 5^\circ \quad (4)$$

Criterion Three. The governing two-dimensional conservation of mass law is expressed in differential form by the following equation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u}{\partial x} + \frac{\partial \rho v}{\partial y} = 0 \quad (5)$$

When the preceeding continuity equation is applied to the mid-span turbine cascade control volume depicted in Figure 6, the equation reduces to the following steady-state, one-dimensional expression:

$$\frac{\partial \rho u}{\partial x} = \dot{m}_1 - \dot{m}_2 = 0 \quad (6)$$

or

$$\dot{m}_1 = \dot{m}_2 \quad (7)$$

Equation 7 is a simple continuity balance which states that the mass flow through the inlet plane is equal to mass flow out the exit plane. Upon substitution of isentropic gas relationships and an algebraic rearrangement of terms (see Appendix B), Equation 7 becomes;

$$\begin{aligned} (\cos \beta_1) M_1 \left(1 + \frac{\gamma-1}{2} M_1^2 \right)^{\frac{\gamma+1}{2(1-\gamma)}} \\ = (\cos \beta_2) M_2 \left(1 + \frac{\gamma-1}{2} M_2^2 \right)^{\frac{\gamma+1}{2(1-\gamma)}} \end{aligned} \quad (8)$$

where

β_1 = gas incidence angle

M_1 = inlet Mach number

β_2 = gas exit angle

M_2 = exit Mach number

Equation 8 is non-dimensional and it relates the cascade inlet conditions to the exit conditions.

The pressure distribution around an airfoil of a typical turbine cascade has been observed to be a function of channel flow characteristics rather than parameters associated

with external airfoil theory. Moreover, for a given airfoil in a cascade, the pressure coefficient distribution is a function of one unique cascade pressure ratio (i.e., mass flow rate):

$$C_p \text{ Distribution} = f(\text{PR}) \quad (9)$$

where

C_p = pressure coefficient

PR = cascade pressure ratio

The pressure coefficient, C_p , is defined as the local static pressure divided by the total pressure. Cascade pressure ratio, PR, is equal to the exit static pressure divided by the total pressure. Exit Mach number, M_2 , can be defined in terms of the cascade pressure ratio, P_2/P_0 , by the following relationship:

$$\frac{P_2}{P_0} = \left(1 + \frac{\gamma-1}{2} M_2^2 \right)^{\frac{\gamma}{1-\gamma}} \quad (10)$$

or

$$M_2 = \sqrt{5 \left[\left(\frac{P_2}{P_0} \right)^{-0.2857} - 1 \right]} \quad (11)$$

where

$$\gamma = 1.4$$

Two points regarding Equation 8 require further clarification. First, the right hand side of Equation 8 remains constant for a given pressure distribution (matching or otherwise) because the gas exit angle is relatively invariant with varying inlet combinations and the exit Mach number is also constant as defined by Equations 11 and 9. Second, for small gas incidence angles, $\cos \beta_1$, is approximately equal to unity. Thus, turbine cascades are insensitive to small gas incidence angles and the inlet Mach number is relatively fixed for a given pressure distribution.

Consequently, if a matching pressure distribution is found such that the first two verification criteria are satisfied, the gas exit angle, β_2 , and the cascade pressure ratio, P_2/P_0 , returned by CASC are a pair of unique quantities. Substitution of these gas exit conditions into Equations 11 and then 8 will yield a relationship which involves only two variables; the inlet Mach number and the gas incidence angle. Hence, the third verification criterion requires that the TDS programs should yield matching pressure distributions for the inlet velocity profile combinations defined by Equation 8, where the right side of the equation is a previously determined constant.

Results

For the specified boundary conditions which define either verification case, analytical pressure distributions were obtained that match the experimental data. At a gas incidence

angle of eight degrees, the inlet Mach number values which yield the matching data are 0.2842 and 0.2990 respectively. Note that the difference between these inlet Mach number values and the Equation 1 approximations are negligible.

The CASC output files for both cases are presented in Appendix C. Figures 7 and 8 are pressure coefficient distribution plots which graphically demonstrate the correlation between the experimental and analytical results.

Comparison of the Figure 7 and 8 curves indicates that a small (1-5 percent) discrepancy exists between predicted and actual data. The analytic pressure coefficients are slightly higher than the corresponding experimental results. This situation occurs primarily because CASC is an inviscid analysis tool. Due to the fact that CASC neglects the presence of boundary layers, it does not consider displacement thickness effects. Thus, lower velocities (higher pressures) are predicted due to larger effective flow areas.

The six to eight percent error associated with the prediction of the minimum throat location is a function of three probable causes. First, boundary layer induced displacement thickness can cause the minimum throat location to shift forward. Second, local blade surface curvature effects from manufacture of the test specimen could also have advanced the minimum area location. Finally, small inaccuracies inherent in the experimental procedure could have accounted for misrepresentation of the minimum throat location.

Figure 7 Case One Pressure Coefficient Distribution

Figure 8 Case Two Pressure Coefficient Distribution

Table IV

Trailing Edge Gas Properties

Test Case	P_2		M_2	β_2 (deg)
	(N/cm ²)	(psia)		
1	10.434	15.1	0.7053	59.64
2	11.052	16.0	0.8275	60.08

Table IV contains the trailing edge conditions returned by CASC for the matching pressure coefficient distributions plotted in Figures 7 and 8. Line pressure losses, ΔP , are calculated by inserting the Table IV exit static pressures into Equation 2. For an atmospheric pressure of 9.885 N/cm² (14.3 psia), the line losses are 0.549 N/cm² (0.8 psi) and 1.167 N/cm² (1.7 psi). These ΔP values satisfy the relationship expressed by Equation 3.

The gas deviation angle, δ , is the difference between the blade outlet angle and the gas exit angle. The computed deviation angles of 1.56° and 1.12° for the two test cases are within the Equation 4 requirements.

In order to satisfy the third verification criterion, the effect of varying the inlet Mach number and gas incidence angle was investigated. A combined total of ninety-one different inlet combinations were analyzed for both cases. Appendices D and E contain the pressure coefficient distri-

Figure 9 Case One Inlet Velocity Profiles
Yielding Matching C_p Distributions

Figure 10 Case Two Inlet Velocity Profiles
Yielding Matching C_p Distributions

bution plots for a representative sampling of the ninety-one point data field.

Figures 9 and 10 were generated from a visual inspection of the entire set of pressure coefficient distributions. Distributions which match the appropriate set of experimental data are plotted as points on a β_1 versus M_1 coordinate system. The matching data collapse along an exit static pressure (P_2) curve whose value is listed in Table IV. This result is predicted by the Equation 9 functional relationship.

A line defined by Equation 8, where the right side of the equation has been evaluated by the Table IV β_2 and M_2 constraints, is superimposed upon the matching data points. The agreement between the locus of expected and calculated matching pressure distributions is excellent. Note that the influence of small gas incidence angles upon the pressure distribution is negligible, while slight Mach number changes will define totally different pressure distribution curves.

Conclusions

The results presented in the previous section satisfy all three verification criteria for the two test cases considered. In addition, the simplifying inlet velocity profile assumptions in the test facility have been substantiated. Thus, the ability of the TDS computer programs to calculate two-dimensional cascade flowfields accurately in the Heat Transfer Facility test environment has been established.

IV. Blade Design Criteria

The objective of this blade design study is to provide the Air Force Aero Propulsion Laboratory with a updated blade profile to be used in an "in-house" turbine cooling test program. The final blade design must be compatible with the static test facility in which the blades are to be tested. The airfoil shape must also exhibit maximum aerodynamic performance in the transonic flow regime specified by AFAPL/TBC.

In order to accomplish the objectives stated above, certain criteria must be established and incorporated into the design process. The threefold intent of this chapter is to define the specified transonic design point, to present the aerodynamic performance standards used for selecting superior designs, and to document a transonic evaluation of the existing design using the previously identified performance standards.

Design Point Operating Conditions

The primary conditions which governed the design of the turbine airfoil were based on the anticipated operating conditions of the test facility in which the blades are to be tested. A compilation of the design point gas properties specified by AFAPL/TBC appears in Table V.

The total pressure and back pressure values listed in Table V are within the operating limits of the test facility

Table V

Design Point Thermodynamic Boundary Conditions

Thermodynamic Quantity		Value	
Description	Symbol	Metric	English
Max Mass Flow Rate	\dot{m}	2.27 kgm/sec	5.00 lbm/sec
Total Temperature	T_o	1666.3 °K	3000.0 °R
Total Pressure	P_o	29.0 N/cm ²	42.0 psia
Back Pressure	P_b	13.1 N/cm ²	19.0 psia
Specific Heat Ratio	γ	1.26	1.26
Gas Constant	R	315.0 $\frac{m^2}{sec^2-°K}$	1883.7 $\frac{ft^2}{sec^2-°R}$

for a mass flow rate less than $2.27 \text{ kg}_m/\text{sec}$ ($5 \text{ lb}_m/\text{sec}$). Together, the two quantities define a transonic environment with an exit Mach number equal to 1.169.

The design point total gas temperature of 1666.3°K (3000°R) is substantially greater than most modern turbine inlet temperatures. However, advanced gas turbines are expected to encounter this type of temperature environment. The AFAPL Heat Transfer Facility has a hot gas temperature generation capability of 2500°K (4500°R) for stoichometric hydrogen-oxidant ratios.

The mass flow rate limitation of $2.27 \text{ kg}_m/\text{sec}$ ($5 \text{ lb}_m/\text{sec}$) is imposed as a constraint because this is the maximum mass flow rate that the facility's compressors can sustain while maintaining a total pressure level greater than 29.0 N/cm^2 (42.0 psia). The gas constant and specific heat ratio are derived from the hydrogen combustion reaction which produces a cascade total inlet temperature of 1666.3°K (3000°R).

Although small gas incidence angles have negligible effect on turbine cascade performance (determined in Chapter III), a design point gas incidence angle of eight degrees was chosen as a best estimate in lieu of firm evidence to the contrary. When the maximum mass flow rate, along with the other Table V thermodynamic quantities, are substituted into Equation 1, the maximum allowable design point inlet Mach number is found to be 0.46.

Aerodynamic Performance Standards

Transonic blade performance is usually measured experimentally because of the inability of present day analytical procedures to successfully model complicated blade trailing edge flowfields where most pressure losses occur. Streamline curvature flow calculation programs, including CASC, require simplifying shock-free and inviscid assumptions which make it impossible to compute an estimate of total pressure losses. Thus, the establishment of aerodynamic performance standards based on minimum pressure loss gives rise to a fundamental question; can the standards be applied to isentropic loss-free CASC predictions? The purpose of this section is to answer the question by presenting a generalized discussion of the theory behind the evaluation of transonic criteria that will be applied to select superior designs.

Trailing Edge Pressure Gradient. The primary function of turbine stator blade rows is to accelerate the working gas medium across a static pressure drop. For a turbine cascade where the flow is subsonic (low pressure ratios), the fluid is accelerated through a convergent flow passage as shown in Figures 2 and 6. The total pressure loss in a subsonic turbine stator row is very small. Viscous losses are of the order of five percent. There are no shock-related losses because the flow is everywhere subsonic. Finally, losses due to separation usually do not occur because the pressure gradients in an accelerating flowfield are favorable.

If the pressure ratio across a blade row is large enough to choke the flow, a sonic line will appear at the flow passage throat location. In a typical convergent turbine cascade, the throat (sonic line) is formed at the trailing edge of a blade's pressure surface and extends to the suction surface of the adjacent blade. The transonic flowfield surrounding the trailing edge of a blade in a convergent turbine stator row is depicted in Figure 11.

At the trailing edge of the Figure 11 blades, the flow over the suction surface is supersonic ($M > 1$). The flow over the pressure surface is subsonic ($M < 1$) until a sonic condition is realized at the trailing edge. Thus, a region of relatively high pressure exists on the lower surface, while a region of low pressure is present on the upper surface. Hence, the existence of an extremely large pressure gradient at the trailing edge of the blades would seem to be indicated.

According to Amana, Demuren and Louis²⁸, this condition is reconciled by an expansion of the flow around the pressure surface trailing edge and then a subsequent compression as the flow turns into the downstream wake (see Figure 11). This phenomena occurs in order to satisfy the Kutta condition of zero pressure gradient at the trailing edge. The compression shock wave formed during this process originates from the trailing edge wake region and then impinges on the suction surface of the adjacent blade. The boundary layer-shock interaction on the suction surface of the blade usually

Figure 11 Trailing Edge Transonic Flowfield

results in flow separation or a change in the boundary layer thickness. This, in turn, changes the suction surface trailing edge boundary conditions and thus, fluctuating (time-dependent) trailing edge pressure gradients are set up. This is the loss mechanism which substantially reduces the performance of convergent cascades under transonic pressure ratios. Amana et al²⁸ and Heinemann²⁹ have reported this phenomenon in literature and they also present corroborating photographic evidence.

Although the CASC program is unable to predict the total pressure losses which accompany these complicated transonic flow patterns, inviscid, shock-free theory can yield a rough estimate of the pressure gradient that must be reconciled at the blade trailing edge due to poor design. Because the pressure gradient is primarily caused by isentropic flow overexpansion on the suction surface and underexpansion on the pressure surface, the CASC estimate of pressure gradient magnitude is an indication of the magnitude of the resultant flow turning, shock strength, and total pressure losses that must occur to satisfy the Kutta condition. Therefore, the first aerodynamic performance criterion requires that the predicted trailing edge pressure gradient is zero.

$$\left. \frac{dP}{dY} \right)_{T.E.} = 0 \quad (12)$$

In order to satisfy the criterion represented by equation 12, the flow on either surface must be expanded to a

single static pressure, i.e., the blade row back pressure. Thus, the flow passage through the stator row will necessarily be convergent-divergent in nature for transonic pressure ratios.

Suction Surface Diffusion. Any number of blade contours can be designed to satisfy the first performance criterion at the design point described in the first section of this report. Thus, a second performance criterion that can be applied to quantitatively distinguish between isentropic CASC results is required.

In the absence of experimental data, it is common analytical design practice to predict aerodynamic performance by estimating the amount of diffusion which occurs on the surface of a given airfoil design. Prince¹⁵, McDonald¹⁷, Szanca and Schum³⁰ address the topic of turbine airfoil diffusion and concur that diffusion control is a significant transonic blade design performance criterion.

Diffusion or flow deceleration causes the formation of adverse pressure gradients which thickens the boundary layer on the surface of the blade. Under rapid or long term decelerations, the flow separates completely. The possibility of a shock wave interaction with the boundary layer of a diffusing flow will almost certainly cause a flow separation. Thus, an inviscid prediction of the amount of diffusion which occurs on the blade suction surface is an indication of the

tendency for the flow to separate and thereby significantly increase pressure losses.

The second performance criterion that will be applied to the various blade designs is summarized in the following statement: the airfoil shape yielding the least amount of flow overexpansion and subsequent diffusion is the better design. This flow overexpansion standard is applied to proposed designs through use of the following equation;

$$\Delta P_{\text{overexpansion}} = P_{\text{sexit}} - P_{\text{sminimum}} \quad (13)$$

Evaluation of Existing Design

The present design was evaluated in terms of the aerodynamic performance criteria developed in the previous section for the transonic design point. Highlighting the deficiencies of the existing airfoil in this manner demonstrates the need for design of a transonically well-behaved blade shape.

Since there is no transonic experimental data for the existing turbine airfoil, the CASC flow analysis was used to obtain predictions of the flowfield surrounding the existing airfoil at the transonic design point. In this case, the CASC input \$BB namelist is exactly the same as those depicted in Appendix A, except that the Table V thermodynamic data are substituted in lieu of the verification operating conditions. For choked, transonic flow cases, CASC iterates

upon the upstream inlet Mach number (mass flow rate), while holding the back pressure constant. CASC also returns exit static pressure for either blade surface that satisfy the isentropic equations and boundary conditions. These calculated exit pressures may or may not equal each other, or the back pressure depending on the design.

Figure 12 is a plot of the pressure distribution resulting from the evaluation investigation. Regions of rapid acceleration can be observed to occur on both the pressure and suction surfaces. Note that the flow over the suction surface overexpands to a very high Mach number (low pressure) immediately behind the sonic throat at 51 percent of axial chord. After this initial overexpansion, the velocity (pressures) on the suction remain relatively constant. Because the flow on the pressure surface does not exceed a Mach number greater than one, a large pressure gradient at the trailing edge is 6.649 N/cm^2 (9.63 psi). The amount of overexpansion which occurs on the upper surface is determined to be 4.197 N/cm^2 (6.08 psi).

The current blade behaves poorly because too much turning occurs on the suction surface after the throat location. After sonic conditions are reached, convex surface curvature causes the remaining suction surface to act as a supersonic diverging nozzle. By the time the turning becomes small, a high velocity has been attained and must be diffused, separated or shocked-down to satisfy the exit conditions and

Figure 12 CASC Prediction of the Transonic Design Point C_p Distribution for the Existing Blade

trailing edge Kutta boundary requirements. Finally, lack of a convergent-divergent flow passage prevents the flow on the pressure surface from undergoing supersonic expansion to reach the exit static pressure level.

V. Parametric Design Study

The geometry of the existing airfoil typifies most subsonic turbine cascades. A turbine airfoil that is designed to operate at subsonic pressure ratios is easily identified by the following geometric characteristics; a convergent flow passage, significant suction surface curvature after the throat location, a maximum blade thickness position at 30-50 percent of axial chord, and a moderate stagger angle. The net effect of these blade shape trends is a turbine cascade that is totally unsuited for transonic flow environments.

During the course of this design study, the observation was made that a well designed transonic cascade exhibits two distinguishing geometric features. First, in order to expand the flow on the pressure surface to the proper exit pressure level, a convergent-divergent flow passage is a necessary hallmark of any transonic turbine cascade. Second, practically all of the suction surface flow turning must occur ahead of the throat location to prevent supersonic overexpansion and subsequent diffusion on that surface.

Consequently, the twofold objective of this parametric design study is to identify the geometric parameters that have a major influence on the two features discussed in the previous paragraph, and then, to determine the parameter combination which yields the maximum amount of aerodynamic performance at the design point operating conditions.

Parametric Design Approach

Two modes of data input to the BLDDDES module were discussed in Chapter II. The parametric option requires utilization of a BLDDDES subroutine called BSGEN, which analytically generates blade surface coordinate arrays using parametric input in lieu of digitized data. The blade section generation (BSGEN) calculation procedure involves the computation of a section meanline derived from a fourth-order polynomial and a thickness distribution derived from the conformal transformation of a fifth-order polynomial. The coefficients of these polynomials are governed by the blade shape input parameters.

When the resulting standardized airfoil definitions are evaluated by the aerodynamic analysis module, CASC, a pressure distribution prediction for the original set of blade shape input parameters is obtained. Four input parameters were found to have a substantial effect upon the airfoil pressure distribution predictions. Thus, the design study was limited to variations of these four input parameters. The influence of each input parameter upon overall aerodynamic performance was determined by generating a total of 72 different blade profiles, and then, evaluating the associated pressure distribution predictions.

The remaining required BLDDDES input parameters were held constant throughout the parametric variation study. These fixed parameters generally tended to relate to the physical dimensions of a given airfoil configuration rather than the blade profile itself. The assigned values chosen for the

fixed parameters are physically compatible with the static test facility.

Definition of Blade Shape Parameters

The primary intent of this section is to identify and adequately describe both the fixed and varied blade shape input parameters. A complete description of the parametric input variables and the BSGEN calculation procedure appears in AFAPL-TR-78-92²⁴.

Fixed Parameters. Table VI contains a listing of the parameters that were assigned fixed values during the parametric variation study. A schematic of the BSGEN coordinate system in which these parameters are employed is presented in Figure 13. The following paragraphs provide a brief description of the parameters tabulated in Table VI.

The velocity vector diagram information that is consistent with the test facility geometry, is represented by the first two Table VI entries. BETAl and BETA2 are the specified gas inlet and gas exit angles respectively. Together, the two quantities fix the amount of flow turning to be accomplished in the cascade passage.

Throat size parameter, CF, influences the size of the flow passage geometric throat or the minimum clearance between blades. The throat is calculated in the following manner;

$$\text{THROAT} = \text{CF} * \text{S} * \cos(\text{BETA2}) \quad (14)$$

Table VI
Fixed Blade Shape Parameters

Parameter	Description	Fixed Value
BETA1	gas inlet angle	8.0°
BETA2	gas exit angle	62.0°
CF	throat size parameter	0.9
C3	meanline curvature control factor	0.1
DELTA1	angle of attack	0.0°
ISTK	stacking point indicator	1
ITMODE	trailing edge shape indicator	1
IVANE	blade-vane indicator	0
NBLDS	number of blades	100
RLE	leading edge section radius	60.6 cm (23.9 in)
RREF	reference radius	60.6 cm (23.9 in)
RTE	trailing edge section radius	60.6 cm (23.9 in)
TE	trailing edge thickness	0.127 cm (0.050 in)
TMAXX	maximum section thickness	0.7798 cm (0.307 in)
ZLE	leading edge axial position	0.0 cm (0.0 in)
ZTE	trailing edge axial position	3.893 cm (1.5327 in)

Table VII
Varied Blade Shape Parameters

Parameter	Description
SF	stagger factor
C1	maximum section thickness location (fraction of axial chord)
C2	trailing edge taper factor
TI	leading edge bluntness factor

Figure 13 Blade Generator Coordinate System

where S is the blade spacing (see Figure 13). Initially, the blade exit angle, α_2 , is set equal to the gas exit angle, β_2 . If the throat (minimum blade clearance) calculated by BSGEN is not equal to the desired throat represented by equation 14, a new blade exit angle is computed. The value chosen for CF insures that the mass flow rate through the test facility will not exceed 2.27 kg_m/sec (5 lb_m/sec).

Although the parameter C3 controls the intermediate curvature of the section meanline, this factor has a minor effect on the overall blade shape when compared to the effects of the varied parameters. The Table VI value for C3 is favorably consistent with decreasing the suction surface unguided turning.

The angle of attack to the blades in the cascade is specified by DELTA1. Since an angle of attack was not desired, DELTA1 was set equal to zero. Because DELTA1 is the angular difference between the tangent line to the section meanline at the leading edge and the inlet velocity vector, the following relationship exists when DELTA1 is zero;

$$\alpha_1 = \beta_1 \quad (15)$$

where α_1 and β_1 are the blade inlet and gas inlet angles respectively.

ISTK, ITMODE, and IVANE are minor blade shape indicators. These quantities were defined in Chapter III and the fixed values listed in Table VI are consistent with the previous

discussion. NBLDS, RLE, RREF, and RTE have been previously defined in Chapter III. The number of blades and the radii lengths that were assigned, define a cylindrical blade section with a cascade blade spacing, S , of 3.894 cm (1.533 in). The cylindrical section is almost rectilinear because of the large radial values chosen. ZLE and ZTE define the axial width of the blades. Note that the blade spacing and axial width for the proposed transonic designs is the same as that for the existing cascade.

Fifty mils is the minimum tolerable trailing edge thickness required for advanced turbine blading with trailing edge coolant holes. The maximum section thickness for typical transonic turbine stators is usually 20 percent of the axial chord length. This general rule-of-thumb was applied to fix TMAXX.

Varied Parameters. The four blade shape input parameters that were varied are listed in Table VII. The input parameter SF, stagger factor, indirectly controls the stagger angle, β_s , in the following way;

$$SF = \frac{\tan \beta_2 - \tan \beta_s}{\tan \beta_s - \tan \beta_1} \quad (16)$$

Hence, the relationship between stagger factor and stagger angle is an inverse function, i.e., increasing SF decreases β_s . The stagger angle of a turbine cascade is an important transonic design parameter. For a given amount of flow

turning (velocity vector diagram), large stagger angles tend to reduce surface curvature in the aft portion of the blades. Blades with high stagger angles are characterized by long, straight tails with relatively no suction surface curvature after the throat location. The primary consequence of increasing stagger angle is to shift most of the flow turning to the foreward portion of the blades, thereby, enhancing transonic performance. Therefore, the stagger factor was treated as a variable design parameter.

The input parameter C_1 , the non-dimensional axial location of maximum section thickness, was also treated as a design parameter. In order to promote higher stagger angles and substantial flow turning ahead of the throat location, most of the blade mass (i.e., maximum section thickness), must be concentrated towards the leading edge of the blade. The maximum section thickness location along with stagger angle primarily determines whether or not the flow passage will have a convergent-divergent nature.

Trailing edge taper factor, C_2 , controls the trailing edge included angle, θ , as defined by the following equation;

$$\theta = 2 \tan^{-1} \left[\sqrt{C_2} \left(\frac{T_{MAXX} - T_E}{Z_{TE} - Z_{LE}} \right) \cos \beta_2 \right] \quad (17)$$

The trailing edge taper factor was considered to be a significant design parameter because trailing edge taper heavily influences the throat location and the ratio of throat to exit area.

Finally, the leading edge bluntness factor, TI, is related to the leading edge radius of curvature as shown in Figure 13. Bluntness increases with increasing TI values. The flowfield behavior over the midchord portion of the blades is a strong function of the leading edge bluntness. Although the parameter TI is somewhat dependent on the maximum section thickness magnitude and location, it has been included as an independent design parameter.

Transonic Performance Maximization

Procedure. The four blade shape input parameters (C1, C2, SF, TI) were systematically varied to generate seventy-two different blade design versions for analysis by the CASC module. Then, the resultant pressure distributions were evaluated in terms of the two aerodynamic performance standards that were developed in Chapter IV.

The specific approach that was used to maximize the relationships between the input parameters and the aerodynamic performance standards was a two phased procedure. Under phase one, the input parameter combinations which yielded designs with trailing edge pressure gradients, off design exit static pressures, etc., were identified and eliminated from consideration. This objective was achieved for four separate values of maximum section thickness location (C1), by varying the other three input parameters until a unique design was found that satisfied the first performance criterion at the design point exit pressure. The second phase

of the performance maximization process was concerned with selecting one of the four design versions from phase one. In phase two, determination of the superior design was based upon the pressure distribution prediction which exhibited the least amount of suction surface diffusion.

The final design selection is presented in the last section of this chapter. Description of the input parameter/aerodynamic performance relationships that were discovered during the parametric variation study is the subject of the next two subsections.

Elimination of Trailing Edge Pressure Gradients. For a given value of maximum section thickness location (C_1), the other three variable blade shape input parameters (SF , C_2 , TI) were individually varied to determine whether or not any characteristic effect upon pressure distribution shape could be attributed to a specific input parameter. Although each of the three input parameters did not exhibit completely uncoupled influences upon the predicted pressure distributions, well-defined aerodynamic trends were related to each input parameter.

The stagger factor, SF , primarily determines the magnitude of the pressure gradient across the blade's trailing edge. If the stagger factor is too large (i.e., the stagger angle is too small) for a given set of operating conditions, the predicted pressure distribution from the resulting blade profile will feature a pressure surface that is underexpanded and a suction surface that is overexpanded. Thus, an increase

in the stagger factor tends to decrease the convergent-divergent nature of the flow passage. A limiting case is encountered when the stagger factor becomes great enough to cause the flow passage to become entirely convergent. The opposite extreme condition is a stagger factor that is too small, which yields a design that has an overexpanded pressure surface and an underexpanded suction surface. Appendix F contains various selected design versions that illustrate proper and improper combinations of these input blade shape parameters. Design version two is an example of a blade contour with not enough stagger angle, while design version eighteen typifies the case with too much stagger angle.

Once the appropriate stagger factor is found such that the trailing edge pressure gradient is eliminated, the input parameter C2 is varied to adjust the trailing edge taper ratio. Although, the trailing edge pressure gradient may be zero, the cascade exit static pressure to which both surfaces are expanded may not necessarily equal the design back pressure. Design version twelve (Appendix F) is an example of a design case where the trailing edge pressure gradient is zero but the exit static pressure is considerably lower than the design back pressure. Decreasing the value of the taper factor has the effect of decreasing the trailing edge included angle (see Equation 17). The ratio of the flow passage throat to exit area is thereby decreased and the exit static pressure of an overexpanded flow is raised. Hence, for a given maximum thickness location and stagger factor, proper positioning

of the throat location with reference to the flow passage exit plane is accomplished by varying the taper factor, C2.

The last variable input parameter that was incorporated into the design parameter investigation, is the leading edge bluntness factor, TI. The combination of stagger factor and taper factor that yields a design with zero trailing edge pressure gradient for a particular exit static pressure is still not a unique combination until the parameter, TI is introduced. The characteristic effect on predicted pressure distribution shape that is associated with leading edge bluntness is midchord overexpansion and recompression phenomena. The predicted pressure distribution for design version fourteen (Appendix F) shows jagged peaks and troughs that are commensurate with unstable flow accelerations and decelerations on the suction surface. A larger amount of leading edge bluntness alleviates this problem.

Versions fifty-two, fifty-nine, sixty-five, and seventy-two are the design versions that exhibited zero trailing edge pressure gradient at the design exit static pressure with no significant midchord overexpansions and recompressions. These four versions respectively correspond to decreasing values of maximum section thickness location.

Table VIII contains a complete listing of the variable input parameter combinations used to generate these design versions. Figures 14, 15 and 16 are plots of SF, C2 and TI versus the maximum section thickness location, C1, for the

four unique design versions which satisfied the first aerodynamic performance standard. The parametric relationships expressed in these figures define the locus of designs which yield maximum aerodynamic performance as a function of maximum section thickness location. Version seventy-two was selected as the best design and therefore, its blade contour, coordinates and predicted pressure distribution appear in the last section of this chapter. The remaining versions are presented in Appendix F.

Minimizing Suction Surface Diffusion. The design versions listed in Table VIII are the superior aerodynamic blade contours for each respective maximum section thickness location. Selection of the best aerodynamic profile is determined from suction surface diffusion considerations. Diffusion data for each of the designs is tabulated in Table IX and plotted in Figure 17.

Application of the second performance criterion to the diffusion data yields version seventy-two as the best overall aerodynamic blade design. Although the Figure 17 diffusion trend indicates that better aerodynamic designs may exist at lower maximum section thickness locations, design versions with maximum section thickness location ahead of the 20 percent axial chord position were not considered due to practical mechanical and thermal limits.

Shifting the maximum section thickness location forward while maintaining a maximum aerodynamic performance profile tends to increase mechanical and thermal stresses. The

effective crosssectional area for interior cooling systems and structural integrity continuously reduces with decreasing C_l values. Not only does the overall crosssectional area become smaller, but the area distribution within the profile changes unfavorably, i.e., the area in the front portion of the blade increases while the area in the already thin aft portion decreases even further.

Because thermal and mechanical analyses were not included within the scope of this study, an arbitrary thermal-mechanical limit was imposed upon the forward movement of the maximum section thickness position. The Figure 14, 15, and 16 relationships can be used to generate new designs should a thermal-mechanical analysis establish that this arbitrary limit is not sufficiently restrictive.

Final Design

On the basis of the preceeding analysis, the blade contour which yielded the maximum amount of aerodynamic performance is design version seventy-two. A scaled drawing of the blade coordinates, a schematic of the cascade formed by the final blade profile, and the predicted pressure distribution of the new transonic design appears in Figures 18, 19, and 20. The blade section profile coordinates are given in Table X. These coordinates are tabulated with respect to an origin located at the leading edge highlight point, and are normalized as a fraction of the axial width, 3.894 cm (1.533 in).

Although the scaling in the two figures is different comparison of the Figure 18 transonic design with the existing subsonic profile depicted in Figure 5 graphically demonstrates the dissimilarities between the two blade contours. The slightly convergent-divergent flow passage geometry of the new transonic turbine cascade is evident in Figure 19. Finally, the inviscid pressure coefficient distribution prediction of the new blade profile (Figure 20), is a significant improvement over the current design (Figure 12), in terms of the Chapter IV performance standards.

VI. Off-Design Performance

An important aspect of turbine blade design is the prediction of cascade performance at off-design operating conditions. Usually, the environment under which the turbine airfoil actually operates is significantly different from the originally intended design operating conditions. Therefore, the new transonic turbine stator design must not only exhibit maximum aerodynamic performance at the transonic design point specified in Chapter IV, but it should exhibit reasonable performance over a wide range of possible test environments.

The four most probable off-design scenarios that the new design is anticipated to encounter are as follows:
1) an angle of attack other than zero, 2) a different gas total temperature, 3) cold flow tests, and 4) an alternate pressure ratio. Hence, the predicted performance of the proposed airfoil design in these off-design test environments is reported in the following sections of this chapter. In addition, the last section is addressed to the topic of viscous boundary layer influence upon aerodynamic performance.

Angle of Attack Sensitivity

The final turbine stator profile presented in Chapter V was designed for an angle of attack equal to zero. However, there is a good possibility that the new design may experience a slight angle of attack if the gas inlet angle in the test

facility is not eight degrees. Although the Equation 8 continuity relationship indicates that turbine cascades are insensitive to small angles of attack, the effect upon performance of both positive and negative angles of attack was analytically investigated.

Pressure distribution predictions for the new airfoil were obtained at off-design gas inlet angles, β_1 , ranging from zero to sixteen degrees. In every case, the results were identical to the pressure coefficient distribution plotted in Figure 20. Thus, the recently designed transonic turbine cascade, sketched in Figure 19, is relatively insensitive to small angles of attack.

Effect of Total Temperature Variations

In accordance with the requirement for a design that is based on an extremely high gas temperature, a design point gas total temperature of 3000°R was selected. At the present time, most cooled or uncooled turbine stators can not withstand these temperatures at transonic blade loadings. Therefore, most cascade tests in the immediate future will probably occur at lower gas total temperatures until superior materials and/or cooling systems are developed.

Thus, the effect of lowering the operating gas total temperature to values of 2000°R and 2500°R was investigated. Since the governing continuity and momentum equations do not have explicit temperature terms, the effect of total temperature variation was expected to be negligible. This outcome

was realized by the resulting lower temperature pressure distributions which were identical to the Figure 20 pressure profile.

Cold Flow Test Conditions

Cold flow tests are conducted in the static test facility on certain occasions. When the nature of the experimental program requires use of low temperature instrumentation, cold flow testing becomes essential. Therefore, the performance of the new design was estimated for operation in this type of test environment.

Although the effect of total temperature variation upon cascade performance was reported to be negligible in the previous section, cold flow test conditions marginally effect aerodynamic performance. The reason for this apparent discrepancy is due to the fact that the major difference between the design point operating condition and cold flow testing is the change in the working gas medium, not the total temperature difference.

During the design point operating condition, the high gas temperatures are generated by an upstream chemical combustion reaction between hydrogen and compressed air. When this combustion reaction does not occur (cold flow), the nature of the working gas medium considerably changes. Thus, it is the specific heat ratio and molecular weight of compressed air at low temperatures which causes the observable difference in aerodynamic performance.

Figure 21 is a plot of the pressure distribution prediction for a cold flow test condition defined by the following thermodynamic quantities;

$$T_o = 300^{\circ}\text{K} \text{ (540}^{\circ}\text{R)}$$

$$\gamma = 1.4$$

$$R = 286.9 \frac{\text{m}^2}{\text{sec}^2\text{-}^{\circ}\text{K}} \left(1716.2 \frac{\text{ft}^2}{\text{sec}^2\text{-}^{\circ}\text{R}} \right)$$

The isentropic pressure distribution prediction returned by CASC indicates that the flow on the suction surface will tend to undergo an increased amount of diffusion until an under-expanded exit pressure of 13.563 N/cm² (19.63 psia) is reached. Meanwhile, the flow over the pressure surface is estimated to overexpand to an exit static static pressure of 12.405 N/cm² (17.96 psia). This situation does not occur in an actual test environment because loss mechanisms, including flow separation and shock wave phenomenon, equalize the trailing edge pressure gradient. Hence, overall aerodynamic performance degrades during cold flow operation. On the basis of the design parameter relationships discussed in Chapter V, this performance problem can be partially alleviated by slightly decreasing the cascade stagger angle, i.e., increase the stagger factor, SF.

Alternate Pressure Ratio

According to the qualitative functional relationship expressed by Equation 9, the pressure coefficient distribution is heavily dependent upon the cascade pressure ratio.

Therefore, both subsonic and transonic off-design pressure ratios were analytically applied to the new design. In terms of significant loss in cascade performance, the results of this off-design pressure ratio investigation are the most dramatic.

Subsonic. An evaluation of the existing design determined that subsonic blade geometries exhibit poor aerodynamic performance at transonic flow conditions. In Chapter V, the geometric qualities which distinguish a subsonic turbine shape from a transonic contour were discussed. This section is concerned with presenting the performance characteristics of the new transonic design with respect to a subsonic pressure ratio.

When the recently developed transonic design is analytically subjected to a subsonic pressure ratio, the isentropic pressure coefficient distribution displayed in Figure 22 is generated. Large amounts of flow overexpansion are predicted on both the pressure and suction surfaces. In fact, the existence of a supersonic bubble on the suction surface is estimated to occur at 30-50 percent of axial chord. Along the divergent portion of the flow passage, flow on both surfaces diffuses drastically. Again, the situation depicted in Figure 22 is not realistic at the trailing edge because flow separation and other loss mechanisms will cause the flows over the aft portion of both surfaces to separate, rather than isentropically diffuse to meet exit static pressure boundary conditions.

Figure 22 Off-Design C_p Distribution Prediction
(Subsonic Pressure Ratio)

Transonic. Figures 23 and 24 show the effect of respectively increasing and decreasing the pressure ratio while maintaining a transonic operating condition. The cascade pressure ratio can be increased by either increasing the total pressure, P_0 , or decreasing the back pressure, P_b . The opposite relationships apply for decreasing the pressure ratio.

Increasing the cascade pressure ratio above the design point enhances the tendency of a negative trailing edge pressure gradient to be predicted, i.e., the suction surface overexpanded and the pressure surface underexpanded. A decrease in the cascade pressure ratio below the design point has the opposite effect; positive trailing edge pressure gradients are predicted. These tendencies are demonstrated in Figures 23 and 24 respectively. Stagger angle can be adjusted to correct these adverse aerodynamic effects in the following manner; reduce stagger angle to compensate for negative pressure gradients, increase stagger angle to compensate for positive pressure gradients.

Effect of Viscous Boundary Layer

The final transonic design is based upon maximization of aerodynamic performance. However, the flowfield calculation procedure and thermodynamic standards utilized to achieve this result are predicted upon isentropic, inviscid theory. In an actual flow situation, viscous boundary layers are present. The overall effect of boundary layer development

Figure 23 Off-Design C_p Distribution Prediction
(Transonic Pressure Ratio above Design Point)

Figure 24 Off-Design C_p Distribution Prediction
(Transonic Pressure Ratio below Design Point)

is the existence of an additional displacement thickness. Since the flow area is reduced, higher velocities result for a given mass flow rate.

This situation was simulated by considering a design version with a slightly larger thickness distribution along the latter portion of the blade. Although the exit static pressures at the trailing edge remain equal, the overall exit static pressure decreases below the design back pressure by 2 percent. Thus, boundary layer induced effects upon performance are relatively insignificant.

VII. Conclusions and Recommendations

A turbine stator profile that is analytically predicted to exhibit good aerodynamic performance over a wide range of transonic operating conditions has been designed for the AFAPL Heat Transfer Test Facility. The design of the new turbine airfoil section was based entirely upon analytical methods. This is a revolutionary approach to the turbine blade design problem. During the course of this design study, a number of significant conclusions were formulated.

First, the analytical TDS computer codes that were used to generate blade profiles and perform cascade flow calculations were verified for accuracy and consistency. Analytical-experimental correlation of TDS pressure distribution predictions with existing test facility cascade data demonstrated the ability of the computer programs to compute heat transfer facility cascade flowfields successfully.

A set of aerodynamic performance standards to be applied to isentropic cascade flowfield solutions has been developed. Although experimental performance data is conclusive, application of isentropic standards to state-of-the-art analytical pressure distribution predictions is less time consuming, more cost-effective, and reasonably valid.

A well designed transonic turbine stator must have a convergent-divergent flow passage with most of the flow

turning occurring ahead of the throat location. Important geometric parameters for the design of transonic turbine airfoils have been identified. Transonic turbine stators require large stagger angles compared with typical subsonic designs. The stagger angle is the critical geometric parameter that determines whether or not the flow is equally expanded on both the pressure and suction surfaces. In addition, the location of maximum section thickness should be positioned ahead of the 25 percent axial chord location in order to minimize diffusion tendencies.

The results of the off-design investigation indicate that the performance of the final transonic design is not seriously compromised at ultimate angles of attack, and total temperature values. However, small changes in the operating pressure ratio will significantly change the pressure distribution of the new design. From an aerodynamic performance or diffusion control viewpoint, operation of the final transonic design at subsonic pressure ratios would be intolerable.

The scope of this transonic turbine stator design study was limited to maximization of aerodynamic performance. Further study is needed to develop a thermal and mechanical analysis suitable for incorporation into the performance maximization process.

A second area requiring further study is development of an improved aerodynamic analysis which incorporates non-

isentropic flow phenomena. For instance, formulation of viscous trailing edge wake model might significantly improve the predicted flowfield calculations.

The final recommendation is that the turbine stator design presented in this report be built and tested in the Air Force Aero Propulsion Laboratory Heat Transfer Test Facility. The results of these experimental tests could provide valuable data regarding the analytical concepts used to generate this design.

APPENDIX B

Derivation of the Non-Dimensional
Turbine Cascade Continuity Equation (Eq. 8)

Equation B-1 is the simple continuity balance which states that the mass flow through the inlet plane is equal to the mass flow out the exit plane. This is equation seven in the text (Chapter III).

$$\dot{m}_1 = \dot{m}_2 \quad (B-1)$$

The subscripts 1 and 2 refer to the turbine cascade inlet and exit stations respectively (see Figure 6). Equation B-1 can be expressed in the Figure 6 terminology;

$$\rho_1 A_1 V_{z_1} = \rho_2 A_2 V_{z_2} \quad (B-2)$$

where

ρ = local density

A = flow area

V_z = axial velocity

It should be readily apparent that the following definitions are valid for a turbine cascade geometry (see Figure 6 control volume):

$$A_1 = A_2 = S \cdot L \quad (B-3)$$

$$V_{z_1} = (\cos \beta_1) V_1 \quad (B-4)$$

$$V_{z_2} = (\cos \beta_2) V_2 \quad (B-5)$$

where

S = cascade pitch (blade spacing)

L = characteristic unit length

β_1 = gas incidence angle

β_2 = gas exit angle

V_1 = inlet velocity

V_2 = exit velocity

Substituting Equations B-3, B-4, and B-5 into Equation B-2 and dividing through by the equal area term yields the following mass flux expression;

$$\rho_1 (\cos \beta_1) V_1 = \rho_2 (\cos \beta_2) V_2 \quad (B-6)$$

From gas dynamic theory, velocity, density and temperature can be represented in the following manner:

$$V = M \sqrt{\gamma R T} \quad (B-7)$$

$$\rho = \frac{P_O}{R T_O} \left(1 + \frac{\gamma-1}{2} M^2 \right)^{\frac{1}{1-\gamma}} \quad (B-8)$$

$$T = T_O / \left(1 + \frac{\gamma-1}{2} M^2 \right) \quad (B-9)$$

Substitution of Equation B-9 into B-7 yields:

$$V = \frac{M \sqrt{\gamma R T_O}}{\sqrt{1 + \frac{\gamma-1}{2} M^2}} \quad (B-10)$$

After the appropriate subscripts are introduced, Equations B-10 and B-8 can be inserted into Equation B-6 to produce the following:

$$\begin{aligned}
& \left(P_O \sqrt{\frac{\gamma}{RT_O}} \right)_1 (\cos \beta_1) M_1 \left(1 + \frac{\gamma-1}{2} M_1^2 \right)^{\frac{\gamma+1}{2(1-\gamma)}} \\
& = \left(P_O \sqrt{\frac{\gamma}{RT_O}} \right)_2 (\cos \beta_2) M_2 \left(1 + \frac{\gamma-1}{2} M_2^2 \right)^{\frac{\gamma+1}{2(1-\gamma)}} \quad (B-11)
\end{aligned}$$

Since no heat transfer and negligible viscous pressure loss is assumed to occur the Figure 6 control volume, the total property terms cancel. Thus, Equation B-11 becomes:

$$\begin{aligned}
& (\cos \beta_1) M_1 \left(1 + \frac{\gamma-1}{2} M_1^2 \right)^{\frac{\gamma+1}{2(1-\gamma)}} \\
& = (\cos \beta_2) M_2 \left(1 + \frac{\gamma-1}{2} M_2^2 \right)^{\frac{\gamma+1}{2(1-\gamma)}} \quad (B-12)
\end{aligned}$$

Vita

Robert Normand Gamache was born on 4 July 1955 in Boston, Massachusetts, the son of Normand R. and Pauline A. Gamache. After graduation from Catholic Memorial High School in West Roxbury, Massachusetts, in 1973, he attended the University of Notre Dame graduating with a Bachelor of Science Degree in Aerospace Engineering in 1977. Upon graduation he received his commission in the United States Air Force through AFROTC. In September 1977, he reported to the Air Force Institute of Technology in the Graduate Aeronautical Engineering Program.

20. ABSTRACT (Continue on reverse side if necessary and identify by block number) A turbine stator profile that is analytically predicted to exhibit good aerodynamic performance over a wide range of transonic operating conditions has been designed for the Air Force Aero Propulsion Laboratory's Heat Transfer Facility. Analytical Turbine Design System computer programs developed by General Electric Company were used to generate blade profiles/coordinates and perform 2-Dimensional cascade throughflow calculations (streamline curvature technique). Two aerodynamic performance

standards were applied to pressure distribution predictions of the blade contours produced from a parametric variation study;

1) equal flow expansion over both the suction and pressure surfaces, and 2) minimum suction surface diffusion. The influence of the following geometric parameters upon the design of a transonic turbine stator were investigated; axial location of maximum section thickness, stagger angle, leading edge bluntness factor, and trailing edge taper factor. Results of this study show that a good transonic turbine stator design must have a convergent-divergent flow passage and a flat suction surface aft of the throat location.
